Abstract

A generic valon potential invariant under $U(1) \times SO(3)$ is used to determine whether the horizontal symmetry of leptons is A_4, S_4, or some other finite subgroups of $SO(3)$. Valons in the potential are assigned $SO(3)$ spins 0, 1, and 2, for these are the only ones that can couple to the three generation of fermions with horizontal spin 1. This potential causes a breakdown into three possible phases with three different symmetries. Phase I has an A_4 symmetry suitable for leptonic mixing. Phase II has an $SO(2)$ symmetry and phase III has a $Z_2 \times Z_2$ symmetry, both capable of describing Cabibbo mixing of quarks. Phase II has to be rejected on phenomenological ground, but phase III yields block diagonal and hierarchical mass matrices appropriate for quarks. No other non-abelian symmetry such as S_4 is present.

I. INTRODUCTION

Symmetry is the foundation of particle physics, so a new symmetry might provide the right key to a door beyond the Standard Model. One candidate is a symmetry of the three fermion generations which interact identically under the Standard Model. Such a (horizontal) symmetry is much discussed, but its existence is not confirmed. Owing to the large mass difference and mixing, if it exists it has to be badly broken. That makes it difficult to be certain of the existence of a symmetry, much less what it is. While mass difference makes it difficult to locate the symmetry, amusingly mixing pattern does help to find it [1].

The hunt for horizontal symmetry received an important stimulus when neutrino mixing was found to be so regular that it could be described by a tri-bimaximal mixing matrix (TBM) [2]. It was also found that this pattern of mixing could be explained by models with an A_4 horizontal symmetry [3]. A_4 is the smallest non-Abelian group that has a three-dimensional irreducible representation, making it attractive because most of the existing symmetries are in some sense described by the smallest possible groups.

Nevertheless, the natural symmetry associated with TBM is the group S_4 [1], not its subgroup A_4. The reason why A_4 works in those models can be traced back to a dynamical choice, allowing an accidental symmetry to promote A_4 to S_4. From the symmetry point of view, S_4 is a more natural group, but it is not the smallest group that A_4 is. Is the leptonic symmetry A_4, or S_4, or something else? One possible way to decide is to appeal to dynamics.

Both A_4 and S_4 are finite subgroups of $SO(3)$, so if the original unbroken horizontal symmetry is $SO(3)$, dynamics of its Higgs valons might determine whether $SO(3)$ breaks down to A_4, or S_4, or some other finite subgroup, thereby telling us what the preferred symmetry of leptons is. It is this possibility that we want to investigate in the present article.

We shall refer to the quantum number of this horizontal $SO(3)$ as *horizontal spin*, but the word 'horizontal' is often omitted for simplicity because we do not discuss any other kind of spin or symmetry here. With three generations of leptons, it is natural to assign them a horizontal spin 1. Valons that couple to them in Yukawa terms must then have horizontal spins 0, 1, and 2. If $SO(3)$ indeed breaks down to S_4 or A_4 in the lepton sector, with the proper vacuum alignments neutrino mixing is automatically TBM, then the three Yukawa

coupling constants can be used to fit the three fermion masses.

Unfortunately it is known that whatever the dynamics is, it is impossible for $SO(3)$ to be spontaneously broken down to either A_4 or S_4, as long as only valons of horizontal spins 0, 1, and 2 are involved [4]. The reason will be reviewed in more detail in the next section, but essentially it is because valons of spins 1 and 2 cannot contain a state invariant under either A_4 or S_4. However, in the case of A_4, there is a spin-2 valon state which differs from an invariant state under an A_4 transformation only by a phase factor. No such state exists for S_4. It is therefore conceivable that in a theory invariant under $U(1) \times SO(3)$, the extra $U(1)$ may provide a compensating phase factor to render this state invariant under A_4, though such an invariant state is still not present in S_4. This is indeed the case as we will show later, so in this way the dynamics of $U(1) \times SO(3)$ chooses A_4 to be the appropriate leptonic symmetry group over S_4. The basic reason for that to be so is because A_4 is a smaller group, so a state invariant under the subgroup A_4 may not be invariant under the full group S_4.

We shall refer to the quantum number of this $U(1)$ as *horizontal charge*.

The extra symmetry $U(1)$ can be understood as providing a second protection for fermion masses. Isospin and hypercharge provides one protection because the left-handed and right-handed leptons have different hypercharge and isospin, preventing a mass term to be formed. Similarly, the valons here possess a non-trivial horizontal charge, forcing the horizontal charges of the left-handed and the right-handed fermions to be different, thereby also forbidding a mass term to be formed. In this way a second protection of the fermion masses is obtained.

A serious impediment to the establishment of a credible horizontal symmetry is the qualitative difference between quark and lepton mixings. Instead of having two large mixing angles as is the case for neutrinos, quark mixings are all small. The regularity of quark mixing is not given by anything resembling a TBM pattern, but merely by a hierarchical structure. Quark mixing is dominated by the mixing of the first two generations, with the mixing of the second and the third generations quite a bit smaller, and that between the first and the third generations the smallest. In the approximation of neglecting the smaller mixings with the third generation, the mixing matrix is block diagonal, with the third generation unmixed. This means that the mass matrices of the up- and down-quarks can be simultaneously put into a block-diagonal form $\mathrm{diag}(m_{12}, m_3)$, where m_3 is the mass of the third generation, and m_{12} is an arbitrary 2×2 matrix from which Cabibbo mixing of the

light masses are determined. We shall refer to a block-diagonal mass matrix of this form as *hierarchical* if $|m_3|$ is much larger than the matrix elements of m_{12}. From the mass spectra of quarks, the mass matrices of the quarks seem to be not only block-diagonal approximately, but also hierarchical.

If horizontal symmetry is really fundamental, how come lepton mixing is governed by a symmetry such as A_4, but quark mixing relies only on a hierarchical structure without any apparent symmetry? Is it possible that this qualitative difference is just an illusion at low energy, with both of them descending from a common symmetry at high energy?

Before proceeding along this line it should be mentioned that models can be constructed in which both quark and lepton mixings are based on A_4, but at the expense of giving up exact TBM. We will not pursue that possibility here.

Interestingly the group $U(1) \times SO(3)$ used to decide the leptonic symmetry to be A_4 could also serve as that common symmetry at high energy. This is because the group breaks spontaneously into three possible phases with different symmetries, some suitable for leptons, and others suitable for quarks. Phase I has a tetrahedral symmetry A_4 that can be employed to explain leptonic mixing, and Phases II and III can produce hierarchical block-diagonal mass matrices that are appropriate for quark mixing. However, Phase II fails because the mixing is between a heavy and a light quark, but Phase III is perfectly viable.

The details of the $U(1) \times SO(3)$ dynamics and the symmetry of the three phases will be dealt with in Sec. III. The fermion mass and mixing matrices in different phases will be discussed in Sec. IV. There are also two appendices containing mathematical details too cumbersome to be discussed in the main text, and a concluding section V.

II. HORIZONTAL SPIN

Suppose $SO(3)$ is a horizontal symmetry at some high energy scale. It was mentioned in the Introduction that no valon potential can break it down spontaneously to A_4 or S_4 if the valons have a horizontal spin less than 3 [4]. The reason for that is reviewed in this section.

If $SO(3)$ can be spontaneously broken down to a subgroup $\mathcal{G}$, then the valon must contain a state invariant under $\mathcal{G}$. Using the known characters of $SO(3)$ and $\mathcal{G}$, we can work out what irreducible representations (IR) of $\mathcal{G}$ that a horizontal spin-J valon contains. The result is shown in Table 1 for $J = 0, 1, 2, 3$, and $\mathcal{G} = A_4, S_4, A_5$.

$\mathcal{G}$	A_4				S_4					A_5				
IR	1	$1'$	$1''$	3	1	$1'$	2	$3'$	3	1	4	5	$3'$	3
$J=0$	1	0	0	0	1	0	0	0	0	1	0	0	0	0
$J=1$	0	0	0	1	0	0	0	0	1	0	0	0	0	1
$J=2$	0	1	1	1	0	0	1	1	0	0	0	1	0	0
$J=3$	1	0	0	2	0	1	0	1	1	0	1	0	1	0

Table 1. Multiplicity of horizontal spin-J state in irreducible representations (IR) of $\mathcal{G}$

Let us see what the table tells us.

1. Other than the trivial $J=0$ state, the only state invariant under $\mathcal{G}$ (transforms like 1) is the $J=3$ state, with $\mathcal{G}=A_4$. There are no invariant states for $J=1$ or $J=2$.

2. Although there is no invariant state for $J=2$ and $\mathcal{G}=A_4$, two of the states $(1', 1'')$ are pseudo-invariant, in that under an A_4 transformation, these states only gain a phase. There is no state in $\mathcal{G}=S_4$ nor $\mathcal{G}=A_5$ which has that property for $J\leq 2$.

3. This observation gives us hope that if we enlarge $SO(3)$ to $U(1)\times SO(3)$, an additional phase from $U(1)$ can be incorporated to cancel the phase of the pseudo-invariant states, thereby turning them into invariant states of A_4. If that is indeed the case, then A_4 could be a descendent of $U(1)\times SO(3)$, though not S_4, nor A_5.

III. U(1) × SO(3) HIGGS DYNAMICS

It will be shown in this section that a generic $U(1)\times SO(3)$ potential of valons with horizontal spins 0 and 2 has three solutions. These solutions differ from one another in order parameters and in symmetry.

Let $\phi=(a_2, a_1, a_0, a_{-1}, a_{-2})$ be a complex valon field with horizontal spin 2, and b a complex valon field with horizontal spin 0. The subscript of a indicates the horizontal angular momentum along some fixed z-axis to be defined later. Let $u(\xi)$ be a member of the $U(1)$ group obeying $u(\xi_1)u(\xi_2)=u(\xi_1+\xi_2)$, and let $u(\xi)\phi=e^{i\xi}\phi,\ u(\xi)\phi^*=e^{-i\xi}\phi^*,\ u(\xi)b=e^{i\xi}b,\ u(\xi)b^*=e^{-i\xi}b^*$. In other words, in additional to the horizontal spin, we also assign ϕ and b a *'horizontal charge'* $+1$ and ϕ^* and b^* a horizontal charge -1.

A real renormalizable Higgs potential of ϕ, ϕ^*, b, and b^* invariant under $U(1) \times SO(3)$ may contain only $\phi^*\phi,\ b^*b,\ \phi^*\phi^*\phi\phi,\ b^*b^*bb,\ b^*b^*\phi\phi,\ \phi^*\phi^*bb$ types of terms. If we choose to couple first $\phi\phi$, and separately $\phi^*\phi^*$, before putting them together in the quartic terms, then the most general Higgs potential can be seen to be

$$\begin{aligned} V &= V_\phi + V_b + V_{\phi b}, \\ V_\phi &= \langle\phi\phi|g_0\mathcal{P}_0 + g_2\mathcal{P}_2 + g_4\mathcal{P}_4|\phi\phi\rangle - \mu^2\langle\phi|\phi\rangle, \\ V_b &= \rho(b^*b)^2 - \nu^2(b^*b), \\ V_{\phi b} &= \tau\langle\phi|\phi\rangle b^*b + \sigma^* b^{*2}\theta + \sigma b^2\theta^*, \end{aligned} \tag{1}$$

where $\mathcal{P}_J$ is the operator projecting into states with horizontal spin J. The reality of V implies that the coupling constants $g_J, \rho, \tau, \mu^2, \nu^2$ are real. The quantity

$$\theta = \sum_{m=-2}^{2} (-)^m a_m a_{-m} \tag{2}$$

is proportional to the component of the compound state $|\phi\phi\rangle$ with zero horizontal angular momentum. See (7) below. The potential V_ϕ, without the μ^2 term, has been used to study d-wave superconductivity, and Bose-Einstein condensates of spin-2 cold atoms [5].

V_ϕ in (1) can be expressed in a more explicit form by getting rid of the projection operators. If $\vec{J}_1$ and $\vec{J}_2$ are the horizontal angular momentum operators of valons 1 and 2, then one relation between the projection operators can be derived by considering

$$\langle\phi\phi|(\vec{J}_1 + \vec{J}_2)^2|\phi\phi\rangle = \langle\phi\phi|0\mathcal{P}_0 + 6\mathcal{P}_2 + 20\mathcal{P}_4|\phi\phi\rangle = 12 + 2\langle\phi|\vec{J}_1|\phi\rangle_1 \cdot \langle\phi|\vec{J}_2|\phi\rangle_2. \tag{3}$$

Choosing the horizontal-spin condensate $\langle\phi|\vec{J}|\phi\rangle$ along the z-axis, we can write $\langle\phi|\vec{J}_1|\phi\rangle_1 \cdot \langle\phi|\vec{J}_2|\phi\rangle_2 = \langle\phi|J_z|\phi\rangle^2 := \langle J_z\rangle^2$. Together with the completeness relation $\mathcal{P}_0 + \mathcal{P}_2 + \mathcal{P}_4 = \mathbf{1}$, we can solve $\mathcal{P}_2$ and $\mathcal{P}_4$ in terms of $\mathcal{P}_0$ to get

$$\mathcal{P}_4 = \frac{1}{7}(3 + \langle J_z\rangle^2 + 3\mathcal{P}_0), \quad \mathcal{P}_2 = \frac{1}{7}(4 - \langle J_z\rangle^2 - 10\mathcal{P}_0). \tag{4}$$

Substituting (4) into (1), and writing $5\langle\phi\phi|\mathcal{P}_0|\phi\phi\rangle = |\theta|^2$, the potential becomes

$$V_\phi = \alpha K^2 + \beta\langle J_z\rangle^2 + \gamma|\theta|^2 - \mu^2 K, \tag{5}$$

where

$$\alpha = \frac{1}{7}(3g_4 + 4g_2), \quad \beta = \frac{1}{7}(g_4 - g_2), \quad \gamma = \frac{1}{5}(g_0 - g_4) + \frac{2}{7}(g_4 - g_2), \tag{6}$$

and

$$K = \langle\phi|\phi\rangle = \sum_m |a_m|^2, \quad \langle J_z\rangle = \sum m|a_m|^2, \quad \theta = \sum(-)^m a_{-m}a_m. \tag{7}$$

No attempt has been made to include couplings with a spin-1 valon in the potential to keep it within manageable complexity. We will simply assume that the presence of a spin-1 valon does not affect the main conclusions reached without it. This would be the case for example if the coupling with it is weak, or that its natural energy scale is much lower than that of the spin-2 or the spin-0 valons. Moreover, as we will see later, the phase diagram obtained from spin-2 valons is not altered by its coupling with a spin-0 valon, so maybe the same thing is true for a coupling with a spin-1 valon as well.

A. Equations of Motion

There are 12 equations of motion, $\partial V/\partial a_m^* = 0 = \partial V/\partial a_m$ $(m = 2, 1, 0, -1, -2)$, and $\partial V/\partial b^* = 0 = \partial V/\partial b$, consisting of the following six and their complex conjugates:

$$\alpha_0 a_m + \beta\langle J_z\rangle m a_m + \gamma(-)^m\theta a_{-m}^* + \tfrac{1}{2}\sigma b^2(-)^m a_{-m}^* = 0 \ , \tag{8}$$

$$\alpha_0 := \alpha - \mu^2/2K + \tau|b|^2/2K \quad ; \tag{9}$$

$$\rho_0|b|^2 b + \sigma^*\theta b^* = 0 \quad , \tag{10}$$

$$\rho_0 := \rho - \nu^2/2|b|^2 + \tau K/2|b|^2 \quad . \tag{11}$$

The cubic equations in a_m, a_m^*, b and b^* are more easily solved by first turning them into quadratic equations of the *order parameters* $K, \langle J_z\rangle, \theta, \theta^*$, and $|b|^2$. This can be achieved by multiplying (8) by a_m^*, and separately by $(-)^m a_{-m}$, then summing over all m. In this way we get

$$\alpha_0 K^2 + \beta\langle J_z\rangle^2 + \gamma|\theta|^2 + \tfrac{1}{2}\sigma b^2\theta^* = 0, \qquad \text{and} \tag{12}$$

$$[(\alpha_0 + \gamma)\theta + \tfrac{1}{2}\sigma b^2]K = 0. \tag{13}$$

It follows that $\sigma b^2\theta^*$ must be real.

Similarly, by multiplying (10) by b^*, we get

$$\rho_0|b|^4 + \sigma^*\theta b^{*2} = 0. \tag{14}$$

Substituting (12) and (14) into (5) and (1), a simplified expression for the Higgs energy emerges:

$$V = -\frac{1}{2}(\mu^2 K + \nu^2 |b|^2) + \frac{1}{4}(\sigma b^2 \theta^* + \sigma^* b^{*2} \theta). \tag{15}$$

B. Solutions

Solutions can be classified by the order parameters $\langle J_z \rangle, \theta, K$, and $|b|^2$. First, assume $b \neq 0$.

$\boxed{b \neq 0}$

Consider separately the cases $\theta \neq 0$ and $\theta = 0$. If $\theta = 0$, then (14) implies $\rho_0 = 0$ and (13) implies $\sigma = 0$. Using (11), we obtain

$$2\rho |b|^2 = \nu^2 - \tau K. \tag{16}$$

Now consider one after another the two cases, $\langle J_z \rangle = 0$ and $\langle J_z \rangle \neq 0$.

I. $\theta = 0, \langle J_z \rangle = 0$. From (8), $\alpha_0 = 0$, hence from (9),

$$2\alpha K = \mu^2 - \tau |b|^2. \tag{17}$$

(16) and (17) can be used to solve $|b|^2$ and K to get

$$|b|^2 = \frac{-\tau\mu^2 + 2\alpha\nu^2}{-\tau^2 + 4\alpha\rho} := |b_I|^2, \quad K = \frac{2\rho\mu^2 - \tau\nu^2}{-\tau^2 + 4\alpha\rho} := K_I. \tag{18}$$

Higgs energy can then be obtained from (15) to be

$$V = V_I := -\frac{\rho\mu^4 + \alpha\nu^4 - \tau\mu^2\nu^2}{-\tau^2 + 4\alpha\rho}. \tag{19}$$

One solution for ϕ that gives rise to $\theta = \langle J_z \rangle = 0$ is

$$\phi_I = \sqrt{\frac{K}{3}} \left(1, 0, 0, \sqrt{2}, 0\right). \tag{20}$$

It will be shown in Appendix A that this solution is unique up to a $U(1) \times SO(3)$ transformation.

II. $\theta = 0, \langle J_z\rangle \neq 0$. (8) implies one and only one a_m is non-zero, and that this cannot be a_0 for otherwise $\langle J_z\rangle = 0$. It is easy to see that $\langle J_z\rangle = mK$, so according to (8) and (9), $\alpha_0 + \beta m^2 = 0$, hence

$$2(\alpha + \beta m^2)K = \mu^2 - \tau|b|^2. \tag{21}$$

K and $|b|^2$ can now be solved from (16) and (21) to give

$$|b|^2 = \frac{-\tau\mu^2 + 2(\alpha + m^2\beta)\nu^2}{-\tau^2 + 4(\alpha + m^2\beta)\rho} := |b_{II}|^2, \quad K = \frac{2\rho\mu^2 - \tau\nu^2}{-\tau^2 + 4(\alpha + m^2\beta)\rho} := K_{II}. \tag{22}$$

Higgs energy is then obtained from (15) to be

$$V = V_{II} := -\frac{\rho\mu^4 + (\alpha + m^2\beta)\nu^4 - \tau\mu^2\nu^2}{-\tau^2 + 4(\alpha + m^2\beta)\rho}. \tag{23}$$

Note that (17) to (19) can be obtained from (21) to (23) simply by setting $m = 0$. The alignment of the spin-2 valon is

$$\phi_{II} = \sqrt{K}(1, 0, 0, 0, 0), \quad \phi'_{II} = \sqrt{K}(0, 1, 0, 0, 0), \tag{24}$$

for $m = 2$ and $m = 1$ respectively. The solutions with $m = -2$ and $m = -1$ can be obtained from these by a π-rotation about the y-axis.

III. $\theta \neq 0$. In this case we must have $\langle J_z\rangle = 0$. Otherwise, as argued before, there is one and only one $a_m \neq 0$, and this is not a_0. As a result, according to (2) or (7), we must have $\theta = 0$, contradicting the assumption that $\theta \neq 0$.

The solution in this case is considerably more complicated because we are no longer forced to have $\sigma = 0$.

Multiply (13) by θ^*, then compare it with (12) and with (14), we get

$$\alpha_0 K^2 + \gamma|\theta|^2 \;=\; \rho_0|b|^4/2, \tag{25}$$

$$(\alpha_0 + \gamma)|\theta|^2 \;=\; \rho_0|b|^4/2, \tag{26}$$

which shows that $|\theta|^2 = K^2$. It also shows that ρ_0 and $\alpha_0 + \gamma$ are both positive, or both negative.

Let us first assume both of them to be negative. Then taking the absolute value of (13) and (10), and use (9) and (11), we get

$$(\alpha_0 + \gamma)K = (\alpha + \gamma)K + \frac{1}{2}(\tau|b|^2 - \mu^2) \;=\; -\frac{1}{2}|\sigma||b|^2, \tag{27}$$

$$\rho_0|b|^2 = \rho|b|^2 + \frac{1}{2}(\tau K - \nu^2) \;=\; -|\sigma|K. \tag{28}$$

These two yield the solution $|b|^2 = |b_{III}|^2$ and $K = K_{III}$, with

$$|b_{III}|^2 = \frac{2(\alpha+\gamma)\nu^2 - (2|\sigma|+\tau)\mu^2}{4(\alpha+\gamma)\rho - (\tau+|\sigma|)(\tau+2|\sigma|)}, \quad K_{III} = \frac{-(\tau+|\sigma|)\nu^2 + 2\rho\mu^2}{4(\alpha+\gamma)\rho - (\tau+|\sigma|)(\tau+2|\sigma|)} \tag{29}$$

They cause the Higgs energy in (15) to be

$$\begin{aligned} V &:= V_{III} = -\frac{\mu^4 N_1 + \mu^2\nu^2 N_2 + \nu^4 N_3}{\left[4(\alpha+\gamma)\rho - (\tau+|\sigma|)(\tau+2|\sigma|)\right]^2}, \\ N_1 &= \rho\left[4\rho(\alpha+\gamma) - \tau(\tau+2|\sigma|)\right], \\ N_2 &= (\tau+2|\sigma|)\left[-4\rho(a+\gamma) + (\tau+|\sigma|)^2\right], \\ N_3 &= \left[-(\tau+|\sigma|)^2(\alpha+\gamma) + 4\rho(\alpha+\gamma)^2\right]. \end{aligned} \tag{30}$$

If both ρ_0 and $\alpha_0+\gamma$ are positive, then the right-hand side of equations (27) and (28) change a sign. In that case, solutions (29) and (30) are still valid provided we change $|\sigma|$ in every expression to $-|\sigma|$.

One spin-2 vacuum alignment that gives rise to $|\theta| = K$ and $\langle J_z\rangle = 0$ is

$$\phi_{III} = \sqrt{K}(\sin\eta/\sqrt{2}, 0, \cos\eta, 0, \sin\eta/\sqrt{2}), \tag{31}$$

where η is an arbitrary angle between 0 and π. It will be shown in Appendix A that all other solutions can be obtained from this one by a $U(1)\times SO(3)$ transformation.

For convenience, these three type of solutions with $b \neq 0$ are summarized in Table 2. The last column indicates the condition under which the solution is valid, and the numbers within parentheses are equation numbers describing the solutions.

sol	$\lvert\theta\rvert$	$\langle J_z\rangle$	$\lvert b\rvert^2$	K	V	ϕ	cond
I	0	0	(18)	(18)	(19)	(20)	$\sigma = 0$
II	0	mK	(22)	(22)	(23)	(24)	$\sigma = 0$
III	K	0	(29)	(29)	(30)	(31)	

Table 2. A summary of the $b \neq 0$ solutions

$\boxed{b = 0}$

It is clear from (10) that there are solutions with $b = 0$. It is also clear from (8) that the solutions for spin-2 valons are identical to those obtained above, after setting $\sigma = \tau = 0$.

From (15), the potential V is also identical to those obtained before by setting $\sigma = \tau = \nu^2 = 0$.

C. Energy and Phases

Stability demands a condensate to have the lowest energy. It is therefore necessary to determine which of the solutions in Table 2 fits that role. The result turns out to depend only on the relative sizes of the parameters α, β, and γ, as shown in the phase diagram in Fig. 1, and not on the parameter τ. Here is how that conclusion is arrived at.

First of all, if $\sigma \neq 0$, then the only solution and the only phase is III, so there is no phase diagram and no need for a further discussion. From now on, we will assume $\sigma = 0$.

The parameters μ and ν have the dimension of energy, and the rest are dimensionless. In the absence of couplings between the (horizontal) spin-2 and spin-0 valons ($\sigma = \tau = 0$), they define the energy scales of the spin-2 condensate K and the spin-0 condensate $|b|^2$, respectively. The spin-0 condensate is given by $|b|^2 = \nu^2/2\rho$, and the spin-2 condensate is given by either I. $K = \mu^2/2\alpha$, II. $K = \mu^2/2(\alpha + m^2\beta)$, or III. $K = \mu^2/2(\alpha + \gamma)$, depending on which of the solution has the least energy. Note that since $|b|^2$ and K are non-negative, the parameters $\rho, \alpha, (\alpha + \gamma), (\alpha + 4\beta)$ must also be non-negative.

The energy V_0 in this un-coupled scenario is given by (15) to be $V_0 = (\mu^2 K + \nu^2|b|^2)/2$, namely,

$$\begin{aligned}
(V_0)_I &= -\left(\frac{\mu^4}{4\alpha} + \frac{\nu^4}{4\rho}\right), \\
(V_0)_{II} &= -\left(\frac{\mu^4}{4(\alpha + \beta m^2)} + \frac{\nu^4}{4\rho}\right), \quad (m = 1, 2), \quad \text{or} \\
(V_0)_{III} &= -\left(\frac{\mu^4}{4(\alpha + \gamma)} + \frac{\nu^4}{4\rho}\right),
\end{aligned} \tag{32}$$

depending on which of the energies is the smallest. If $\beta, \gamma > 0$, the lowest energy occurs in phase I. If $\beta < 0$, II has a lower energy than I, and $m = 2$ always has a lower energy than $m = 1$, hence $m = 1$ is never the condensate and we will consider it no further. If $\gamma < 0$, then II is still the condensate if $4|\beta| > |\gamma|$, otherwise III is the condensate. The phase diagram based on this discussion is shown in Fig. 1.

If τ is not zero, the formulas are complicated and the detail is relegated to Appendix B. Nevertheless, it turns out that Fig. 1 remains valid for all τ, at least for those solutions

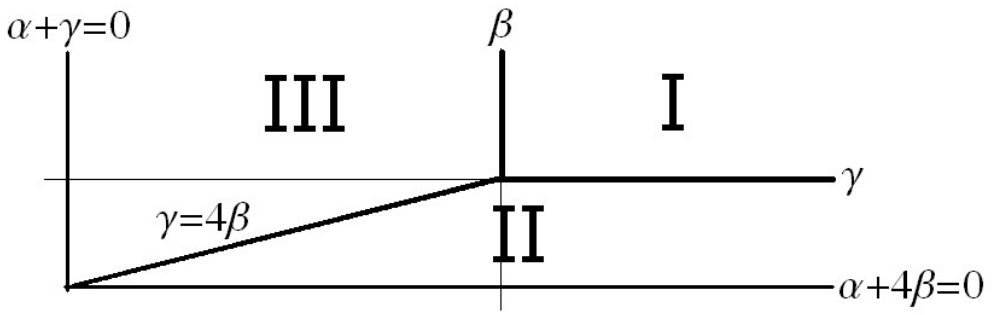

FIG. 1: Phase diagram

defined and connected continuously to the un-coupled solutions.

D. Symmetry of Solutions

Each of the three solutions in Table 2 is invariant under some symmetry group $\mathcal{G} \subset U(1) \times SO(3)$. One way to determine the symmetry is to use Wigner's $\mathcal{D}$-matrix to compute $\sum_{m'} a_{m'} \mathcal{D}^{J=2}_{m'm}(\alpha', \beta', \gamma')$, and equate it to $a_m e^{-i\rho'}$ for some $U(1)$ phase $e^{-i\rho'}$. The Euler angles of rotations are denoted here by α', β', γ', with a prime to tell them apart from the coupling constants in (1) and (6). This gives us five equations ($-2 \leq m \leq 2$) to solve for four unknowns $\alpha', \beta', \gamma', \rho'$. If there is no solution other than $\alpha' = \beta' = \gamma' = 0$, then there is no non-trivial symmetry. Otherwise, the solution of $(\alpha', \beta', \gamma')$ yields the $SO(3)$ element and $e^{i\rho'}$ the $U(1)$ element in $\mathcal{G}$.

I. Tetrahedral Symmetry

The solution $\phi_I = \sqrt{K/3}(1, 0, 0, \sqrt{2}, 0)$ has a tetrahedral symmetry. It is invariant under the two $U(1) \times SO(3)$ operations

$$g_I = e^{-i\beta_0 J_y} e^{-i\pi J_z}, \quad \tilde{g}_I = e^{4\pi i/3} e^{-2\pi i J_z/3}, \tag{33}$$

with $\sin(\beta_0/2) = \sqrt{2/3}$ and $\cos(\beta_0/2) = 1/\sqrt{3}$. Their explicit spin-2 matrix representations

are $\tilde{g}_I = \omega^2 \mathcal{D}^{J=2}(0,0,2\pi/3) = \mathrm{diag}(1,\omega,\omega^2,1,\omega)$, and

$$g_I = \mathcal{D}^{J=2}(0,\beta_0,\pi) = \frac{1}{9}\begin{pmatrix} 1 & 2\sqrt{2} & 2\sqrt{6} & 4\sqrt{2} & 4 \\ 2\sqrt{2} & 5 & 2\sqrt{3} & -2 & -4\sqrt{2} \\ 2\sqrt{6} & 2\sqrt{3} & -3 & -2\sqrt{3} & \sqrt{6} \\ 4\sqrt{2} & -2 & -2\sqrt{3} & 5 & -2\sqrt{2} \\ 4 & -4\sqrt{2} & 2\sqrt{6} & -2\sqrt{2} & 1 \end{pmatrix}. \tag{34}$$

They can be used to verify the invariance $g_I\phi_I = \phi_I$ and $\tilde{g}_I\phi_I = \phi_I$.

These two operators satisfy

$$g_I^2 = \tilde{g}_I^3 = (g_I\tilde{g}_I)^3 = \mathbf{1}, \tag{35}$$

so they generate an A_4 group, the invariant group of a tetrahedron. Note that the $U(1)$ phase factor in (33) is not necessary for $\tilde{g}_I$ to be a generator of $\mathcal{G}_I = A_4$, but it is necessary for ϕ_I to be invariant under $\tilde{g}_I$.

II. Ferromagnetic Symmetry ($m = 2$)

The solution $\phi_{II} = \sqrt{K}(1,0,0,0,0)$ of (24) is invariant under the operation $g_{II} = u(2\xi)e^{-i\xi J_z}$ for any ξ, hence $\mathcal{G}_{II} = SO(2)$.

Originally there were two additive quantum numbers, the horizontal charge Q and the third component of the horizontal spin m. In the ferromagnetic phase, only $m' = m - 2Q$ is conserved. This is reminiscent of the Standard Model, in which both hypercharge and weak isospin are broken in the Higgs phase, leaving the electric charge to be the only additively conserved quantum number.

III. Nematic Symmetry

The solution $\phi_{III} = \sqrt{K}(\sin\eta/\sqrt{2}, 0, \cos\eta, 0, \sin\eta/\sqrt{2})$ is invariant under $g_{III} = e^{-\pi i J_z}$, $\tilde{g}_{III} = e^{-\pi i J_y}$, and $\overline{g}_{III} = e^{-\pi i J_x}$. Any two of those three will generate the symmetry group $\mathcal{G}_{III} = Z_2 \times Z_2$ valid for any η in ϕ_{III}.

At special η's, the symmetry group is enlarged to $SO(2)$. At $\eta = 0$, $\phi_{III} \propto (0,0,1,0,0)$ is invariant under any rotation about the z-axis. At $\eta = \pi/3$, $\phi_{III} \propto (\sqrt{3},0,\sqrt{2},0,\sqrt{3})$ is invariant under any rotation about the y-axis, and at $\eta = 2\pi/3$, $\phi_{III} \propto (\sqrt{3},0,-\sqrt{2},\sqrt{3})$ is invariant under any rotation about the x-axis.

These symmetries of the three phases are summarized in Table 3. Note that the generators need a $U(1)$ factor in I and II, but not III.

sol	η	ϕ	$\mathcal{G}$	$g, \tilde{g}$
I		$\sqrt{\frac{K}{3}}\left(1,0,0,\sqrt{2},0\right)$	A_4	$e^{-i\beta_0 J_y}e^{-i\pi J_z},\ e^{4\pi i/3}e^{-2\pi i J_z/3}$
II		$\sqrt{K}(1,0,0,0,0)$	$SO(2)$	$u(2\xi)e^{-i\xi J_z}$
III	η	$\sqrt{K}\left(\frac{1}{\sqrt{2}}\sin\eta,0,\cos\eta,0,\frac{1}{\sqrt{2}}\sin\eta\right)$	$Z_2\times Z_2$	$e^{-\pi i J_z},\ e^{-\pi i J_y}$
	0	$\sqrt{K}(0,0,1,0,0)$	$SO(2)$	$e^{-i\xi J_z}$
	$\pi/3$	$\sqrt{\frac{K}{8}}\left(\sqrt{3},0,\sqrt{2},0,\sqrt{3}\right)$	$SO(2)$	$e^{-i\xi J_y}$
	$2\pi/3$	$\sqrt{\frac{K}{8}}\left(\sqrt{3},0,-\sqrt{2},0,\sqrt{3}\right)$	$SO(2)$	$e^{-i\xi J_x}$

Table 3. Symmetry of the spin-2 solutions

IV. MASS MATRIX AND MIXING

We will discuss in this section how to compute mass matrix and fermion mixing for the three phases. Phase I with an A_4 symmetry is presumably suitable for leptons. Phases II and III with a hierarchical structure are potentially good for the quarks, but phase II turns out to be unphysical because its main mixing is between a heavy and a light quark.

The mass matrix in these phases is most easily computed when valons are expressed in a matrix form. The following subsection shows how this can be done for valons of horizontal spins 0, 1, and 2.

A. Valons in matrix form

In the Cartesian basis, a spin-2 valon is described by a traceless symmetric matrix (or tensor) $\Phi = (\Phi_{ij})$ $(i,j = 1,2,3$ or $x,y,z)$, whose entries are given by the components of the spin-2 state $\phi = (a_2, a_1, a_0, a_{-1}, a_{-2})$ to be

$$\Phi = \begin{pmatrix} \frac{1}{2}(a_2+a_{-2}) - \frac{1}{\sqrt{6}}a_0 & \frac{i}{2}(a_{-2}-a_2) & \frac{1}{2}(a_{-1}-a_1) \\ \frac{i}{2}(a_{-2}-a_2) & -\frac{1}{2}(a_2+a_{-2}) - \frac{1}{\sqrt{6}}a_0 & \frac{i}{2}(a_{-1}+a_1) \\ \frac{1}{2}(a_{-1}-a_1) & \frac{i}{2}(a_{-1}+a_1) & \frac{2}{\sqrt{6}}a_0 \end{pmatrix}. \tag{36}$$

The normalization is chosen so that $K := \sum_m |a_m|^2 = \mathrm{Tr}(\Phi^\dagger\Phi)$. With that normalization, the scalar θ is given by $\theta = \sum_m (-)^m a_m a_{-m} = \mathrm{Tr}(\Phi^2)$. The three components of the vector

$\langle \vec{J} \rangle$ is proportional to the three independent components of the anti-symmetric hermitian matrix $[\Phi^\dagger, \Phi]$, with $\langle \vec{J}^{\,2} \rangle = \langle J_z \rangle^2 = (\sum_m m|a_m|^2)^2 = -2\mathrm{Tr}([\Phi^\dagger, \Phi]^2)$.

Valons of spin 0 and spin 1 may also be expressed as matrices. The matrix form B of a spin-0 valon b, and Γ of a spin-1 valon $c = (c_1, c_2, c_3)$ in the Cartesian basis, are

$$B = \frac{1}{\sqrt{3}} \begin{pmatrix} b & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & b \end{pmatrix}, \quad \Gamma = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & c_3 & -c_2 \\ -c_3 & 0 & c_1 \\ c_2 & -c_1 & 0 \end{pmatrix}. \tag{37}$$

Normalization is chosen so that $\mathrm{Tr}(B^\dagger B) = |b|^2$ and $\mathrm{Tr}(\Gamma^\dagger \Gamma) = \sum_i |c_i|^2 := |c|^2$.

Under an $SO(3)$ transformation, $A \to h^\dagger A h$ for $A = \Phi, B$, and Γ, where h is the three-dimensional representation of the $SO(3)$ rotation *in the Cartesian basis*, obtained from $\mathcal{D}^{J=1}(\alpha', \beta', \gamma')$ through a similarity transformation that converts spherical basis into Cartesian basis.

In particular, the matrix expressions of the three condensates ϕ_I, ϕ_{II}, and ϕ_{III} are

$$\Phi_I = \frac{1}{2}\sqrt{\frac{K}{3}} \begin{pmatrix} 1 & -i & \sqrt{2} \\ -i & -1 & \sqrt{2}i \\ \sqrt{2} & \sqrt{2}i & 0 \end{pmatrix}, \quad \Phi_{II} = \frac{\sqrt{K}}{2} \begin{pmatrix} 1 & -i & 0 \\ -i & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$
$$\Phi_{III} = \sqrt{\frac{K}{6}} \begin{pmatrix} -\cos\eta + \sqrt{3}\sin\eta & 0 & 0 \\ 0 & -\cos\eta - \sqrt{3}\sin\eta & 0 \\ 0 & 0 & 2\cos\eta \end{pmatrix}. \tag{38}$$

For a generic η, Φ_{III} is invariant under the rotations generated by any pair of the inversions $x \to -x,\ y \to -y,\ z \to -z$, reflecting its nematic structure $Z_2 \times Z_2$.

For Φ_I and Φ_{II}, the explicit form of $h_I, \tilde{h}_I$, h_{II}, the three-dimensional Cartesian representations of the $SO(3)$ operators $g_I = e^{-i\beta_0 J_y} e^{-\pi i J_z}$, $\omega \tilde{g}_I = e^{-2\pi i J_z/3}$, $u(-2\xi) g_{II} = e^{-i\xi J_z}$, are

$$h_I = \frac{1}{3} \begin{pmatrix} 1 & 0 & 2\sqrt{2} \\ 0 & -3 & 0 \\ 2\sqrt{2} & 0 & -1 \end{pmatrix}, \quad \tilde{h}_I = \frac{1}{2} \begin{pmatrix} -1 & -\sqrt{3} & 0 \\ \sqrt{3} & -1 & 0 \\ 0 & 0 & 2 \end{pmatrix}, \quad h_{II} = \begin{pmatrix} \cos\xi & -\sin\xi & 0 \\ \sin\xi & \cos\xi & 0 \\ 0 & 0 & 1 \end{pmatrix}. \tag{39}$$

Using them, the correct transformations

$$h_I^\dagger \Phi_I h_I = \Phi_I, \quad \tilde{h}_I^\dagger \Phi_I \tilde{h}_I = \omega \Phi_I; \qquad h_{II}^\dagger \Phi_{II} h_{II} = e^{-2i\xi} \Phi_{II} \tag{40}$$

can be verified to be true.

B. Fermion Mass Matrices

With the left-handed and right-handed fermions taken to be horizontal vectors, the mass matrix M is just the expectation values of valons they couple to, expressed in the matrix form:

$$M = \Phi + B + \Gamma. \tag{41}$$

The fields a_m, b, c_i in this formula should be interpreted as expectation values. We will assume they can be assigned any value that suits the phenomenology. No Yukawa coupling constant appears because they have been absorbed into the fields.

In order to gain a qualitative understanding of the three phases, let us examine the simplest case when the expectation values are given only by the condensates in the last section. Namely, Φ is given by (38), and $B = \Gamma = 0$.

The squared-mass spectra in these three phases can then be obtained from the eigenvalues of $\overline{M} := M^\dagger M = \Phi^\dagger \Phi$ to be

I. $\frac{K}{3}, \frac{K}{3}, \frac{K}{3}$.

II. $0, 0, K$

III. $K(\overline{s} - \overline{c})^2,\ K(\overline{s} + \overline{c})^2,\ 4K\overline{c}^2$, where $\overline{s} = \sin\eta/\sqrt{2}$ and $\overline{c} = \cos\eta/\sqrt{6}$.

On the surface solution II seems to be tailored made for quark mixing: the mass matrix (38) has a block diagonal form and the mass spectrum is hierarchical, with one heavy mass K and two light masses 0. The trouble is, one of the light masses comes from the unmixed 33 entry. Since both the up- and the down-quark mass matrices have these properties, quark mixing occurs only in the 1-2 block, giving rise to a mixing between a heavy quark and a light quark, not between two light quarks. The inclusion of B and Γ will not change the behavior qualitatively, so phase II has to be rejected on phenomenological grounds. However, the remaining two phases will be put to good use as we shall see in the next two subsections.

C. Quark Sector (Phase III)

In order to force the mixing to be between the first two generations, we will assume only $c_3 \neq 0$ when the vector acquires an expectation value. In that case the mass matrix is

$$M = \Phi_{III} + B + \Gamma = \begin{pmatrix} \sqrt{K}(-\overline{s}+\overline{c}) + b' & c_3' & 0 \\ -c_3' & -\sqrt{K}(\overline{s}+\overline{c}) + b' & 0 \\ 0 & 0 & 2\sqrt{K}\overline{c} + b' \end{pmatrix}, \tag{42}$$

where $\overline{c} = \cos\eta/\sqrt{6},\ \overline{s} = \sin\eta/\sqrt{2},\ b' = b/\sqrt{3}$, and $c_3' = c_3/\sqrt{2}$. This matrix has the correct block-diagonal form. It can be made hierarchical by adjusting the three parameters K, b, η so that the 33-entry is much bigger than the 11- and 22-entries. We will assume η to be in the second quadrant so that the hierarchical mass spectrum $m_1 < m_2 < m_3$ can be obtained with b' and $\overline{s}$ positive, $\overline{c}$ negative, and $|\overline{s}| \gg |\overline{c}|$. We shall also assume $c_3' := i\gamma$ to be purely imaginary. In that case M is hermitian and it can be diagonalized by a unitary matrix.

Since the third generation stands by itself, we need to consider only the submatrix m_{12} in the upper-left block. It can be diagonalized using the formula

$$\begin{pmatrix} \cos\theta & -i\sin\theta \\ -i\sin\theta & \cos\theta \end{pmatrix} \begin{pmatrix} \alpha & i\gamma \\ -i\gamma & \beta \end{pmatrix} \begin{pmatrix} \cos\theta & i\sin\theta \\ i\sin\theta & \cos\theta \end{pmatrix} = \begin{pmatrix} m_1 & 0 \\ 0 & m_2 \end{pmatrix}, \tag{43}$$

where

$$m_1 + m_2 = \alpha + \beta = 2(b' - \sqrt{K}\overline{s}), \quad m_2 - m_1 = \sqrt{(\beta-\alpha)^2 + 4\gamma^2} = -2\sqrt{K}\overline{c}\ .$$
$$\tan 2\theta = \tfrac{2\gamma}{\beta-\alpha} \quad , \tag{44}$$

The constants K, b, η can be fixed from the three quark masses m_1, m_2, m_3. Adjusting the relative size between γ and $\beta - \alpha$, the angle θ can be chosen to be anything we want. The diagonalization matrix is unitary but not orthogonal, but it differs from an orthogonal matrix just by some column and row phase factors which we are allowed to insert by adjusting the phases of the up and down quarks. Thus the Cabibbo angle is just the difference of the θ-angles for the down and the up quarks, something that is up to us to adjust.

This simple quark model is presented to illustrate that Cabibbo mixing with hierarchical quark mass matrices can be accommodated in the nematic phase III.

D. Lepton Sector (Phase I)

Before plunging into the construction of a horizontal-spin model of leptons in phase I, it is useful to recall the representations of A_4, and how trimaximal as well as tri-bimaximal mixings are obtained.

A_4 has four irreducible representations (IR), $\underline{1}$, $\underline{1}'$, $\underline{1}''$, and $\underline{3}$. The representation of its generators g_I and $\tilde{g}_I$, satisfying the relations $g_I^2 = \tilde{g}_I^3 = (g_I\tilde{g}_I)^3 = 1$, is given in Table 4 in the basis where $\tilde{g}_I$ is diagonal ($\omega = e^{2\pi i/3}$).

IR	$\underline{1}$	$\underline{1}'$	$\underline{1}''$	$\underline{3}$
$\tilde{g}_I$	1	ω	ω^2	$\mathrm{diag}(1,\omega,\omega^2)$
g_I	1	1	1	$\frac{1}{3}\begin{pmatrix} -1 & 2 & 2 \\ 2 & -1 & 2 \\ 2 & 2 & -1 \end{pmatrix}$

Table 4. Irreducible representations of A_4

We shall refer to the basis used in Table 4 as the 'F basis', and denote the $\underline{3}$-representation of g_I and $\tilde{g}_I$ there as j_I and $\omega^2\tilde{j}_I$. They differ from the corresponding $SO(3)$ elements h_I and $\tilde{h}_I$ in (39) only by a unitary transformation,

$$u := \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & i & 0 \\ 1 & -i & 0 \\ 0 & 0 & \sqrt{2} \end{pmatrix}, \quad h_I = u^\dagger j_I u, \quad \tilde{h}_I = u^\dagger \tilde{j}_I u. \tag{45}$$

When both the left-handed and the right-handed fermions are A_4 triplets, the Yukawa valons coupled to them belong to $\underline{1}$, $\underline{1}'$, $\underline{1}''$, $\underline{3}_s$, or $\underline{3}_a$, where $\underline{3}_s$ is a triplet that couples symmetrically to the two fermions, and $\underline{3}_a$ a triplet that couples anti-symmetrically. To obtain trimaximal mixing, we should assign the expectation value of a valon in the charged-lepton (neutrino) sector to be an invariant eigenvector of $\tilde{g}_I$ (g_I), for every irreducible representation. If that is not possible then the expectation value shoud be taken to be zero. With this assignment trimaximal mixing is guaranteed. Once a trimaximal mixing is thus obtained, an appropriate adjustment of the Yukawa coupling constants can promote the mixing into a tri-bimaximal mixing.

To implement this procedure in the $U(1)\times SO(3)$ theory where $g_I = e^{-i\beta_0 J_y}e^{-i\pi J_z}$ and $\tilde{g}_I = \omega^2 e^{-2\pi i J_z/3}$, it is necessary to identify the nine A_4 states in representations $\underline{1}$, $\underline{1}'$, $\underline{1}''$, $\underline{3}_s$, $\underline{3}_a$

from the nine horizontal states endowed with horizontal spins 0, 1, and 2. The spin-0 and spin-1 valons are B and Γ in (37). As to the spin-2 state, we assume it either comes from the dynamical valon $\Phi' := \Phi - \Phi_I$ acquiring a vacuum expectation value at a lower energy, or a new low-energy spin-2 valon which does not participate in the high energy dynamics that determines the phase structure. To simplify writing in the first scenario, which we will implicitly assume from now on, the prime will be omitted. Instead, we will replace Φ in (41) by $\Phi_I + \Phi$. Equivalently, in the spherical basis, ϕ is to be replaced by $\phi_I + \phi$.

It is obvious from Table 4 and the explicit form of $g_I, \tilde{g}_I$ that the spin-0 state is a $\underline{1}''$ of A_4. The spin-2 state ϕ can be decomposed into a mixture of $\underline{1}, \underline{1}', \underline{3}$ of A_4 as follows. We already know that $(1, 0, 0, \sqrt{2}, 0)$ transforms like $\underline{1}$. Using (34) it is easy to verify that $(0, -\sqrt{2}, 0, 0, 1)$ transforms like $\underline{1}'$. After projecting these two out, what remains transforms like $\underline{3}$. In this way the decomposition of a spin-2 state $\phi = (a_2, a_1, a_0, a_{-1}, a_{-2})$ is obtained.

$$\begin{aligned}
\phi_1 &= \frac{1}{3}(a_2 + \sqrt{2}a_{-1})\left(1, 0, 0, \sqrt{2}, 0\right) := \sqrt{3}e\left(1, 0, 0, \sqrt{2}, 0\right), \\
\phi_{1'} &= \frac{1}{3}(a_{-2} - \sqrt{2}a_1)\left(0, -\sqrt{2}, 0, 0, 1\right) := \sqrt{3}d\left(0, -\sqrt{2}, 0, 0, 1\right), \\
\phi_3 &= \frac{1}{3}\left(2a_2 - \sqrt{2}a_{-1},\ a_1 + \sqrt{2}a_{-2},\ 3a_0,\ a_{-1} - \sqrt{2}a_2,\ 2a_{-2} + \sqrt{2}a_1\right), \\
\phi &= \phi_1 + \phi_{1'} + \phi_3. \qquad (46)
\end{aligned}$$

ϕ_3 is a 5-dimensional vector with 3 independent components. It can be projected into the $\underline{3}$ space to get

$$v = (v_1, v_2, v_3) = \frac{1}{\sqrt{3}}(-a_1 - \sqrt{2}a_{-2},\ \sqrt{3}a_0,\ -a_{-1} + \sqrt{2}a_2) := \phi\mathcal{P}. \qquad (47)$$

The components of v are chosen to commute with the $SO(3)$ rotations, so that $(\phi g_I)\mathcal{P} = (\phi\mathcal{P})f_I$ and $(\phi\tilde{g}_I)\mathcal{P} = (\phi\mathcal{P})\omega^2\tilde{f}_I$, where f_I and $\tilde{f}_I$ are the $SO(3)$ *part* of the spin-1 A_4 generators in the spherical base, namely, $\tilde{f}_I = \mathrm{diag}(\omega^{-1}, 1, \omega)$ and

$$f_I = -\frac{1}{3}\begin{pmatrix} 1 & 2 & 2 \\ 2 & 1 & -2 \\ 2 & -2 & 1 \end{pmatrix}. \qquad (48)$$

These two differ from the $\underline{3}$ representation $j_I = g_I$ and $\tilde{j}_I = \omega^{-2}\tilde{g}_I = \mathrm{diag}(\omega, \omega^2, 1)$ in the last column of Table 4 only by an inconsequential unitary transformation W,

$$W := \begin{pmatrix} 0 & 0 & 1 \\ -1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \quad j_I = W f_I W^\dagger, \quad \tilde{j}_I = W\tilde{f}_I W^\dagger. \qquad (49)$$

They also differ from h_I and $\tilde{h}_I$ of (39) just by a unitary transformation C that converts spherical harmonics into Cartesian coordinates:

$$C = uW^\dagger = \frac{1}{\sqrt{2}} \begin{pmatrix} -1 & i & 0 \\ 0 & 0 & \sqrt{2} \\ 1 & i & 0 \end{pmatrix}, \quad h_I = C^\dagger f_1 C, \quad \tilde{h}_I = C^\dagger \tilde{f}_1 C. \tag{50}$$

The normalization of v is chosen so that its norm $|v|^2 := \sum_i |v_i|^2 = |\phi_3|^2 := \sum_m |(\phi_3)_m|^2$.

Besides the spin-2 valon ϕ, the mass matrix M also receives contribution from the spin-0 valon b which is a $\underline{1}''$, and the spin-1 valon c which is a $\underline{3}_a$ because Γ is an anti-symmetric matrix.

Next, let us compute the expectation value of valons needed to yield trimaximal mixing. Those used in the charged-lepton mass matrix M_e are given by the invariant eigenvectors of $\tilde{g}_I$, and those used in the neutrino mass matrices M_ν are given by the invariant eigenvectors of g_I. In case the operator does not have an eigenvalue $+1$, the corresponding expectation value is zero. The solution to this requirement is summarized in Table 5. Normalization cannot be determined so those listed in Table 5 are really vacuum alignments, computed in the F-basis where $\tilde{g}_I$ is diagonal. The vectors v_F and c_F are vectors v and c expressed in that basis. The table also gives relations between a_m and between c_i needed to obtain such vacuum alignments. They can be computed either from the invariant eigenvectors v_F and c_F, or more directly from the condition that $\tilde{h}_1^\dagger M_e \tilde{h}_1 = \omega M_e$ and $h_1^\dagger M_\nu h_1 = M_\nu$.

valon	e	d	v_F	b	c_F
IR	$\underline{1}$	$\underline{1}'$	$\underline{3}$	$\underline{1}''$	$\underline{3}$
M_e	1	0	$(1,0,0)$	0	$(1,0,0)$
			$a_1 = a_0 = a_{-2} = 0$		$c_1 = c_3 = 0$
M_ν	1	1	$(1,1,1)$	1	$(1,1,1)$
			$-\sqrt{2}a_2 + a_1 + a_{-1} + \sqrt{2}a_{-2} = 0$		$c_1 = \sqrt{2}c_3$
			$-\sqrt{2}a_2 + \sqrt{3}a_0 + a_{-1} = 0$		$c_2 = 0$

Table 5. Vacuum alignment of horizontal valons

Using Table 5, we obtain the F-basis mass matrix $u(\Phi_I + \Phi + B + \Gamma)u^\dagger$ to be

$$M_e = \begin{pmatrix} 0 & a'_2 & 0 \\ 0 & 0 & a'_{-1}/\sqrt{2} - \sqrt{2}c_2 \\ a'_{-1}/\sqrt{2} + \sqrt{2}c_2 & 0 & 0 \end{pmatrix},$$

$$M_\nu = \begin{pmatrix} -v'_3 + b' - ic_3 & e' + 2v'_3 & d - v'_3 + ic_3 \\ d + 2v'_3 & b' - v'_3 + ic_3 & e' - v'_3 - ic_3 \\ e' - v'_3 + ic_3 & d - v'_3 - ic_3 & b' + 2v'_3 \end{pmatrix}, \quad (51)$$

where $\kappa = \sqrt{K/3},\ a'_2 = a_2 + \kappa,\ a'_{-1} = a_{-1} + \sqrt{2}\kappa,\ e' = e + \kappa,\ b' = b/\sqrt{3}$, and $v'_3 = v_3/\sqrt{6}$.

In this F-basis, $j_I M_\nu j_I^\dagger = M_\nu$ and $\tilde{j}_I^\dagger M_e \tilde{j}_I = \omega M_e$. Although $\tilde{j}_I$ is diagonal, M_e is not because of the phase factor ω. However, this phase factor cancels out in $\overline{M}_e = M_e^\dagger M_e$ so $\overline{M}_e$ is diagonal, with eigenvalues $m_e^2 = (\sqrt{2}c_2 + a_{-1}/\sqrt{2})^2,\ m_\mu^2 = a_2^2,\ m_\tau^2 = (\sqrt{2}c_2 - a_{-1}/\sqrt{2})^2$. They can be used to determine the parameters c_2, a_2, a_{-1} from the masses of the charged leptons. In particular, c_2 and a_{-1} must have opposite signs to yield the correct hierarchy of masses.

The expression for M_ν in (51) can be used for the Dirac mass matrix of the neutrinos as well as the Majorana mass matrix of the heavy right-handed neutrinos, with two different sets of parameters of course. This matrix is *magic* because the sum of every row and every column is equal to $b' + d + e'$, hence the mixing matrix is trimaximal [6]. If we choose the parameters such that $e' = d$ and $c_3 = -3iv'_3$, then the mixing matrix is 2-3 symmetric and hence bimaximal [6]. With this choice, the neutrino mixing matrix is both trimaximal and bimaximal so it has the TBM form.

V. CONCLUSION

We propose to resort to dynamics to determine which of the finite non-abelian subgroups of $SO(3)$ is the appropriate horizontal symmetry of leptons. We do so by using dynamics of valons of horizontal spin not larger than 2, invariant under the smallest group containing $SO(3)$ that can spontaneously break down to at least one non-abelian subgroup. It is found that using $U(1) \times SO(3)$, the only non-abelian subgroup it can break down to is A_4, thereby making it the preferred horizontal symmetry of leptons. Other than A_4, this dynamics also produces two other phases, a phase II with a $SO(2)$ symmetry, and a phase III with a $Z_2 \times Z_2$ symmetry, both capable of describing Cabibbo mixing of the quarks with a mass hierarchy. It turns out that phase II yields the wrong mass hierarchy and has to be rejected, but phase III is perfectly viable. Thus $U(1) \times SO(3)$ can also be thought of as a common high-energy horizontal symmetry where both the Cabibbo mixing of quarks and the tri-

bimaximal mixing of neutrinos originate. Explicit mass matrices in the quark sector (phase III) and in the lepton sector (phase I) are constructed to illustrate these features.

Technical complication prevented us from including a fully coupled spin-1 valon into the potential in this paper. CP violation is also left out. To include the latter it is presumably necessary to go beyond $SO(3)$ to $SU(3)$. These points are being investigated. There are also several other dynamical issues that requires further study. For example, we have assigned phase I to the lepton sector and phase III to the quark sector because that seems to be what phenomenology demands, but it would be much nicer if a dynamical mechanism can be found to force that to happen automatically. This paper is of an exploratory nature, to test the idea and to demonstrate the feasibility of a symmetry group common to the quark and lepton sectors, a higher group that can even select the lepton symmetry at lower energies. It is not meant to present a complete dynamical model so detailed questions such as whether this higher symmetry is local or global, and the associated question of Goldstone bosons, etc., have all been left out.

I am grateful to Fei Zhou, We-Fu Chang, and James Bjorken for stimulating discussions. Part of this work was carried out while visiting the Theoretical Science Center at Tsinghua University in Hsinchu, and the Academia Sinica in Taipei, in the summer of 2010, whose hospitality I would also like to acknowledge.

Appendix A: Uniqueness of the spin-2 solutions

The purpose of this appendix is to show that the $\langle \vec{J}^2 \rangle = \langle J_z \rangle^2 = 0$ solutions (20) and (31) are unique up to $U(1) \times SO(3)$ transformations.

As discussed in Sec. IV, a spin-2 valon ϕ can be represented by a traceless symmetric matrix Φ, with $\langle \phi | \phi \rangle = \mathrm{Tr}(\Phi^\dagger \Phi)$, $\theta = \mathrm{Tr}(\Phi^2)$, and $\langle \vec{J}^2 \rangle = -2\mathrm{Tr}([\Phi^\dagger, \Phi]^2)$.

Since $[\Phi^\dagger, \Phi]$ is hermitian, $[\Phi^\dagger, \Phi]^2$ is positive semi-definite, with non-negative real eigenvalues. To have a zero trace needed for $\langle \vec{J}^2 \rangle = 0$, all eigenvalue must be zero, implying $[\Phi^\dagger, \Phi] = 0$. Therefore $\Phi^\dagger$ and Φ can be simultaneously diagonalized by an orthogonal transformation.

Suppose $\mathrm{diag}(a, b, -a-b)$ is the diagonal form of the traceless matrix Φ. Applying a $U(1)$ transformation if necessary we may assume a to be real. The θ parameter is given by

$$\theta = \mathrm{Tr}(\Phi^2) = 2(a^2 + b^2 + ab). \tag{A1}$$

If $\theta = 0$, then it is still zero if we multiply both sides of (A1) by a or by b. Equating these two identities, we get $a^3 = -a(b^2 + ab) = -b(ab + a^2) = b^3$. Therefore b/a is a third root of unity. This root cannot be 1 for then $\theta \neq 0$, hence it must be $\omega = e^{2\pi i/3}$ or $\omega^2 = e^{4\pi i/3}$. Thus the eigenvalues of Φ are $a,\ a\omega$, and $a\omega^2$. Since a is fixed by the norm $K = \langle \phi | \phi \rangle = \mathrm{Tr}(\Phi^\dagger \Phi)$ to be $a = \pm\sqrt{K/3}$, the solution Φ for $\theta = J_z = 0$ is unique up to a sign and a $U(1) \times SO(3)$ transformation, hence ϕ_I in (20) is unique up to a $U(1) \times SO(3)$ transformation.

As a check, we can compute directly the eigenvalues of Φ_I. They turn out to be $\sqrt{K/3}$, $\sqrt{K/3}\,\omega$, and $\sqrt{K/3}\,\omega^2$.

If $|\theta| = K$, with a $U(1)$ transformation we can render $\theta = K$. In that case $\theta = a^2 + b^2 + (a+b)^2 = K = |a|^2 + |b|^2 + |a+b|^2$. Since a is real, so must be b. As a function of b, a reaches a stationary point at $a = -2b$, whence $\theta = 3b^2 = K$, giving $b = \pm\sqrt{K/3}$ and $a = \mp 2\sqrt{K/3}$. We can now parametrize a to be $a = 2\sqrt{K/3}\cos\eta$. Substituting this into (A1) with $\theta = K$, we can solve b to get $b = \sqrt{K/3}(-\cos\eta \pm \sqrt{3}\sin\eta)$. Thus the eigenvalues of Φ are $\sqrt{K/3}(2\cos\eta, -cos\eta + \sqrt{3}\sin\eta, -\cos\eta - \sqrt{3}\sin\eta)$. Comparing this with the expression for Φ_{III} in (31), we see that the η here is the same as the η there. It also shows the uniqueness of ψ_{III} up to a $U(1) \times SO(3)$ transformation.

Appendix B: Interacting condensates

The dependence of V, K, $|b|^2$ on τ and σ will be worked out in this appendix for phases I, II, and III. We will also work out what the phase diagram Fig. 1 becomes when $\tau \neq 0$.

For the sake of this discussion, we shall assume the spin-2 condensate in the absence of coupling to be larger than the spin-0 condensate, namely, $\sqrt{\alpha}\nu^2/\sqrt{\rho}\mu^2 := r < 1$.

1. $\theta = 0,\ \langle J_z \rangle = 0$

The condensates are given in (18) and the energy in (19).

First consider how V_I changes with τ. At $\tau = 0$, $V_I = (V_0)_I = -(\mu^4/4\alpha + \nu^4/4\rho)$. Since $(dV_I/d\tau)_{\tau=0} = \mu^2\nu^2/4\alpha\rho$ is positive, $|V_I|$ decreases with increasing τ in the vicinity of $\tau = 0$. Farther away, V_I has two stationary points where $dV_I/d\tau$ vanishes. The smaller one is located at $\tau = \tau_- := 2\alpha\nu^2/\mu^2 := \tau_0 r$, where $\tau_0 := 2\sqrt{\alpha\rho}$, and the larger one is located at $\tau_+ = \tau_0/r$. V_I reaches a local maximum $(V_I)_- = -\mu^4/4\alpha$ at τ_- and a local minimum $(V_I)_+ = -\nu^4/4\rho$ at τ_+. The local maximum is smaller (lower) than the local minimum because $r < 1$. The sum of the values at the local maximum and local minimum happens to be the value V_I at $\tau = 0$.

There are two asymptotes located at $\tau = \pm\tau_0$ where $V_I = \pm\infty$. They divide the graph of V_I vs τ into three branches. Since $0 < \tau_- = \tau_0 r < \tau_0$, the smaller stationary point appears in the central branch. The other stationary point at $\tau_+ = \tau_0/r > \tau_0$ is to be found in the right-hand branch.

The left-hand branch starts at $V_I = 0$ at $\tau = -\infty$ and rises monotonically to $+\infty$ at the left asymptote $\tau = -\tau_0$. The central branch starts at $V_I = -\infty$ at the left asymptote, rises to a maximum at $\tau = \tau_-$, then drops back to $-\infty$ at the right asymptote. The right-hand branch starts at $V_I = +\infty$ at the right asymptote, descends to a minimum at $\tau = \tau_+$, then rises back to 0 at $\tau = +\infty$.

The central branch is sketched in Fig. 2.

Next, let us see how the condensates b^2 and K vary with τ. At $\tau = 0$, $b^2 = \nu^2/2\rho$ and $K = \mu^2/2\alpha$. The product of these two happens to be the slope of V_I at that point. Both of the b^2- and K-slopes at $\tau = 0$ are negative. b^2 decreases monotonically from the value $\nu^2/2\rho$ at $\tau = 0$ to the value 0 at $\tau = \tau_-$, beyond which b^2 becomes negative and

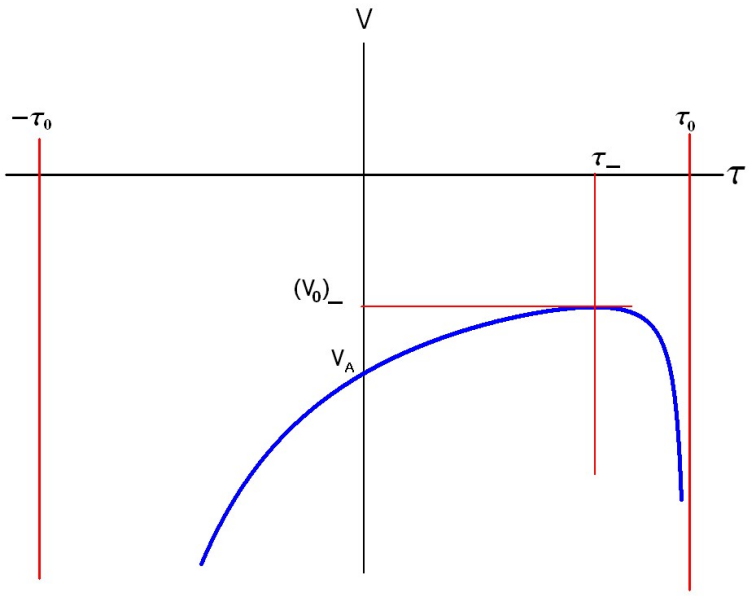

FIG. 2: The center branch of the Higgs potential V_I vs τ

unacceptable. For that reason we need not consider the central branch in Fig. 2 to the right of τ_-. The condensate K starts from the value $\mu^2/2\alpha$ at $\tau = 0$, decreases to a minimum value $(\mu^2/2\alpha)(r/2\zeta)$ at $\tau = \tau_m = \zeta\tau_0$, where $\zeta := (1 - \sqrt{1-r^2})/r$. From $\tau = \tau_m$ to τ_-, K increases from this minimum back to the value $\mu^2/2\alpha$. To be consistent, we should have $\zeta < 1$ and $r < 2\zeta$, which indeed follows from the condition $0 < r < 1$.

For negative τ, both b^2 and K increase monotonically to the value $+\infty$ at the left asymptote $\tau = -\tau_0$.

The behavior of b_I^2, K_I, and V_I is summarized in Table 5. The definition of various τ_a is given in the second row, with $r := \sqrt{\alpha}\nu^2/\sqrt{\rho}\mu^2$ and $\zeta := (1 - \sqrt{1-r^2})/r$. Also, $\xi := r^2/2 + r/2\zeta - 1$. It follows from $0 < r < 1$ that $0 < r/2 < \zeta < r$ and $0 < \xi < r^2$. Hence b^2 and V are monotonic in the range $-\tau_0 < \tau < \tau_-$, but K has a minimum located at $\tau = \tau_m$.

τ	$-\tau_0$	0	τ_m	τ_-
def	$-2\sqrt{\alpha\rho}$	0	$\zeta\tau_0$	$r\tau_0$
b^2	$+\infty$	$\nu^2/2\rho$	$\nu^2/4\rho$	0
K	$+\infty$	$\mu^2/2\alpha$	$(\mu^2/2\alpha)(r/2\zeta)$	$\mu^2/2\alpha$
V	$-\infty$	$-(\mu^4/4\alpha)(1+r^2)$	$-(\mu^2/4\alpha)(1+\xi)$	$-\mu^4/4\alpha$

Table 5. The variation of (18) and (19) with τ in the case of $\theta = \langle J_z \rangle = 0$

2. $\theta = 0,\ \langle J_z \rangle = 2K$

The condensates in this phase are given in (22) and the energy given in (23), both with $m = 2$. In particular, V_{II} in (23) is the same as V_I in (19) after having α replaced by $\alpha' = \alpha + 4\beta$.

Since

$$\frac{\partial V_I}{\partial \alpha} = \frac{(-2\rho\mu^2 + \nu^2\tau)^2}{(-\tau^2 + 4\alpha\rho)^2} \geq 0, \tag{B1}$$

phase II has a higher (lower) energy than phase I if $\beta > 0$ (< 0). In other words, the boundary between phases I and II in the phase diagram of Fig. 1 remains the same even if the coupling $\tau \neq 0$ is turned on.

3. $|\theta| = K,\ \langle J_z \rangle = 0$

The condensates in this phase are given in (29) and the energy given in (30).

If $\sigma = 0$, then (29) can be obtained from (19) by replacing α with $\alpha'' = \alpha + \gamma$. On account of (B1), the boundaries of phase III with phases I and II remain the same as Fig. 1 even in the presence of τ-coupling.

If $\sigma \neq 0$, the τ-dependence is very complicated. However, if the spin-0 condensate b^2 is non-zero, the solutions in phases I and II do not exist for $\sigma \neq 0$, so this phase III remains the only phase no matter what τ is.
